Abstract

In this paper, we consider the computation of the instantaneous dynamic response of actuated multi-rigid-body systems subject to Coulomb frictional constraints. Such systems are difficult to analyze due to nonlinearities arising from transitions between different contact modes, as well as potential ambiguities and inconsistencies in their solution. We report an enumerative algorithm capable of computing the unknown accelerations and contact forces in such systems, subject to contact constraints through a linear complementarity (LCP) formulation as well as arbitrary, model-specific equality and inequality constraints. In doing so, we identify subsets of the control input space that correspond to specific contact modes, a useful characterization for the design of model-based controllers. We illustrate the application of these computational tools on the problem of dynamic self-righting of a hexapod robot through simulation studies.

Keywords: Rigid body dynamics, contact modeling, dynamic flipping, static indeterminacy, dynamic indeterminacy, Coulomb friction

I. Introduction

Robotic systems most often interact with their environment through explicitly or involuntarily established frictional contacts. Manipulation of either the robot or the environment through such interactions, especially for tasks which critically depend on accurate control of contact reaction forces, is a challenging problem. The primary difficulty is in modeling interactions between two objects in contact, where choices regarding contact compliance, frictional models, treatment of impact, and other conditions have significant impact on the complexity, accuracy and tractability of the end result. Increasing model complexity leads to difficulties in building model based controllers as the computational cost associated with the resulting algorithms becomes prohibitive for their practical deployment. Finally, accuracy through complexity often sacrifices analytical tractability and makes it difficult to draw general conclusions about stability and performance.

In this paper, we develop a general method to solve for the instantaneous model response for controlled dynamic planar multi-rigid-body systems with Coulomb frictional contact constraints. The main contribution of our method is an algorithm which computes for such systems, the instantaneous dynamic response — unknown accelerations and reaction forces — as a function of system state and externally applied control inputs. In doing so, we are able to rigorously characterize well-known problems associated with frictional contacts such as multiplicity and non-existence of solutions. This characterization also provides a concise representation of constraints on the space of control inputs to ensure particular modes for each contact, yielding a method that can effectively be utilized in the design of controllers that are capable of reliably regulating their interaction with their environment.

In order to illustrate practical application of our general modeling tool, we present a controller design for the self-righting of an hexapod robot. RHex is an autonomous robot capable of operating outdoors on rough and highly broken terrain [29]. Dynamic running on such unstructured conditions sometimes results in loss of balance and tum-
bling, resulting in upside-down body orientations. Even though RHex’s morphology is mostly symmetric with respect to the horizontal plane, there are still several reasons to preserve its nominal orientation including higher locomotion efficiency and applications such as vision based navigation.

The motivation for addressing this problem and basic principles for the construction of model-based flipping controllers were previously introduced in [30]. In this paper, we develop a new controller which is based on the same ideas, but capable of significantly extending the domain of validity and robustness of the earlier “blind” controller. Most notably, we are able eliminate all of its empirically motivated assumptions on the progression of particular contact modes throughout behavior execution. However, due to the higher sensory demands and computational complexity of the new controller, we are only able to provide simulation studies for a comparative characterization of the new controller. Nevertheless, we present qualitative evidence to establish the accuracy of our simulated model with respect to earlier experiments on RHex.

Even though we choose RHex’s flipping as our primary application domain in this paper, the presented techniques are equally applicable to problems such as climbing with snake-like robots. Characteristic features of these platforms, such as the large number of degrees of freedom and their reliance on frictional contact for various forms of locomotion, result in highly flexible and minimally invasive exploration capabilities [7]. These very same features also make the analysis and control of climbing behaviors for such systems more challenging. Analysis which explores these challenges for similar climbing systems is reported in [5] and [22]. The general method presented in this paper is a step towards the deployment of useful controllers for such settings as well.

The paper is organized as follows. In Section II, we outline related research in the field of rigid-body dynamics and control with Coulomb friction as well as dynamic manipulation for legged robots. In Section III, we introduce our algorithm for calculating the dynamic response of multi-rigid-body systems under frictional contact, including a characterization of potential multiplicity of solutions. In Section IV, we apply our technique to the problem of flipping with the RHex hexapod robot. Finally, in Section V we provide a conclusion and outline future directions for our research.

II. Related Research

Modeling and analysis of rigid bodies subject to frictional contact constraints received some attention in the robotics literature. Rajan, Burridge and Schwartz [28] and Erdmann [9] are among the first robotics researchers to explore inconsistencies and ambiguities arising from combining rigid-body models with Coulomb friction. In [28] the authors consider the dynamics of a planar rigid body in contact with one or two walls. The space of applied wrenches is partitioned into regions that correspond to particular contact modes and overlaps between these regions reveal solution ambiguities. Erdmann [9] gives an extensive characterization of solutions for the motion of a planar rigid body under a single externally applied force and one contact point. The author characterizes inconsistency and ambiguity of solutions through the relation of friction cones to an obstacle in the configuration space, further generalizing this result to multi-contact solutions for a single rigid body.

Modern work in this area [2], [17], [20], [25], [31], [32] largely focuses on modeling multi-rigid-body system dynamics under friction using the Linear Complementarity Problem (LCP) framework. Among others, a class of formulations exemplified by Pfeiffer and Glocker [25] expresses LCP constraints of multi-rigid-body systems as a function of forces and accelerations in the system. Our approach in this paper adopts this general framework, even though we do not incorporate explicit models of impact such as Newton and Poisson models, or consider tangential impacts as presented in [25] that can serve to resolve frictional inconsistency. Trinkle et al. [32] extend the LCP framework formulated as a function of contact forces and accelerations to three dimensional systems through a linearization of the friction cone. The authors present existence and uniqueness conditions for solutions, under the assumptions that
all coefficients of friction are small and system Jacobians have full column rank.

In contrast to formulations of contact constraints as a function of forces and accelerations, complementarity conditions can also be posed as a function of velocities and contact impulses through a time discretization of the system dynamic response. These methods are claimed to be capable of more cleanly addressing Painlevé type problems, where no non-impact solution exists, through a more natural and uniform treatment of impacts. For example, Anitescu and Potra [2] formulate a “time-stepping” LCP formulation wherein they are able to guarantee the existence of solutions in all cases, even though solution multiplicity still remains as an issue. The advantages of such time-stepping formalisms are also discussed in Stewart’s work [31].

It is only recently that the problem of control in the context of rigid-body dynamics with frictional contact started receiving more attention in the literature. Balkcom and Trinkle [3] consider ambiguities between non-fixed contact modes and generalize the notion of strong stability, posed earlier by [23] in the context of fixturing. They present an algorithm capable of determining the cone of permissible wrenches to yield a particular contact mode between two slow-moving planar rigid bodies, based on polyhedral convex cone operations developed by [12]. The algorithm presented is used to design a controller for a workpiece insertion task. Notable limitations of this work include the assumption of negligible velocities and a single rigid body as well as the requirement that the task be expressible solely in terms of a desired contact mode. Nevertheless, the methods introduced in the present paper are largely motivated by their work.

In a more recent line of research, Peng, Anitescu, and Akella [24] formulate the problem of optimal control under frictional contact as a mathematical program with complementarity constraints (MPCC) and consider multi-robot coordination in the plane as their application domain. Considerable further development in solving MPCC by consideration of their elastic mode is presented in the work by Anitescu [1]. Further research in the area of control under contact constraints includes work by Huang and McClamrock [14], which considers optimal control of dynamical systems subject to complementarity constraints but neglects friction and focuses primarily on impacts. Work by Prattichizzo and Bicchi [26] characterizes the stability, controllability, and observability of frictional systems by introducing lumped compliance at contacts and replacing unilateral constraints with bilateral constraints to prevent contacts from separating or sliding. Finally, Brogliato explores control problems under friction in the general context of control of complementary systems and poses a series of open questions pertaining to the controllability and stabilizability of such systems [6].

Our application domain of robotic self-righting closely relates to the literature on dynamic behaviors for legged robots. Raibert’s work on dynamically stable hopping robots [27] was influential in the development of various other systems capable of performing dynamical maneuvers such as biped gymnastics [13] and brachiating robots [21]. However, in most of these cases, models of environment interaction through contact have been simplified using assumptions of infinite friction (“sticky” feet) or specific mode sequences. In contrast, the problem of dynamic self-righting considered in this paper critically relies on more accurate models of ground interactions and pronounces many of the advantages for our general modeling tool for controlled dynamics of multi-rigid-body systems with frictional contacts.

Most mobile robots designed to operate in unstructured environments avoid the necessity to perform self-righting maneuvers by adopting morphologies which are symmetric with respect to the horizontal plane [19]. There have only been a few robots which are explicitly capable of performing such maneuvers [10], [11], [33], but their use of special kinematic structures (for example, long extension arms or reconfigurable wheels) is not suitable for RHex’s limited actuation affordance and morphology [29]. Consequently, the dynamic flipping controllers first introduced in [30], and further extended in this paper to more robustly handle models of frictional contact represent a novel approach in performing dynamic maneuvers with legged robots.
III. CONTROLLED DYNAMICS OF SYSTEMS WITH FRICTIONAL CONTACTS

In a multi-rigid-body system subject to frictional contacts, the unknown dynamic quantities are \( \dot{q} \) and \( f \), the generalized accelerations and contact reaction forces of the system, respectively. Developing a model which predicts these dynamic quantities as function of control torque is crucial in the model-based control of such systems.

Ideally, we would like to be able to compute the dynamic response function in its most general form

\[
\begin{bmatrix}
\dot{q} \\
f
\end{bmatrix} = g(q, \dot{q}, \tau),
\]

(1)

For unconstrained mechanical systems, the calculation of this function involves only linear operations such as matrix inversion and the resulting solution is always linear in the control inputs \( \tau \). On the other hand, computing the same function for a mechanical system subject to Coulomb friction constraints is more involved, as the instantaneous dynamic response is no longer linear, but rather piecewise linear in the control inputs. Furthermore, additional complications arise from possible multiplicity or non-existence of solutions for certain control inputs.

As a consequence, the above form of the dynamic response function (1) is generally not well-defined for frictionally constrained systems. Instead, we adopt the slightly more general form

\[
\begin{bmatrix}
\dot{q} \\
f
\end{bmatrix} = g(q, \dot{q}, \tau, w),
\]

(2)

where the vector \( w \) accounts for solution ambiguities. We further partition the domain of this function into a number of subsets, each of which correspond to a particular contact mode and yields a linear relation between \( (\dot{q}, f) \) and \( (\tau, w) \) for a given system state \( (q, \dot{q}) \). A more formal definition of this function together with an algorithm for its computation will be detailed in subsequent sections.

A. Modeling of System Dynamics

Our algorithm presumes the availability of a Lagrangian formulation of the system dynamics, with generalized coordinates \( q \in \mathbb{R}^q \) providing a local minimal representation of the configuration of the system when unconstrained by contact. We assume that there are \( k \) contact points and each has a local inertial coordinate frame \( X_i := (p_i, t_i, n_i) \) with origin located at \( p_i \), defined such that \( n_i \) is normal to the contact surface and outward from the environment, and \( (t_i, n_i) \) forms a right-handed coordinate system.

For a uniform treatment of contact constraints and reaction forces, we express the position of each contact point on the mechanism in the corresponding contact frame \( X_i \), through the kinematic map

\[
\begin{bmatrix}
x \\
\end{bmatrix} = h(q),
\]

where we have \( x := (x_{n_i}, x_{t_i}, ..., x_{n_i}, x_{t_i}) \in \mathbb{R}^{2k} \). These kinematics also yield the contact Jacobian matrix \( J := D_q h \) that relates velocities and accelerations of contact points of the mechanism to the generalized coordinates through the relations

\[
\begin{align*}
\dot{x} &= J \ddot{q} \\
\ddot{x} &= J \ddot{q} + \dot{J} \dot{q}.
\end{align*}
\]

(3)

(4)

Dynamical equations governing the motion of the system hence take the form

\[
M(q) \ddot{q} + C(q, \dot{q}) \dot{q} + g(q) = \tau + J^T f,
\]

(5)

where \( \tau \in \mathbb{R}^t \) and \( f = (f_{n_1}, f_{t_1}, ..., f_{n_k}, f_{t_k}) \in \mathbb{R}^{2k} \) denote known external control inputs and initially unknown contact reaction forces respectively; the latter being expressed in local contact coordinates.

B. Contact Modes and Constraints on Dynamics

In an LCP framework for modeling the dynamics of a rigid-body system subject to Coulomb frictional contacts, each contact has associated complementarity constraints on corresponding accelerations and reaction forces. By definition, a complementarity constraint between two variables requires that both variables are non-negative and at least one of them is zero. For example the normal contact acceleration and the normal contact reaction force for all contacts are constrained to be complementary.

Complementarity conditions arising from non-penetration of two planar rigid bodies, combined with the Coulomb friction model result in the definition of four different contact
modes for each contact [18]: separating (S), sliding left (L) or right (R) or fixed (F). Each contact point hence has an associated contact mode

\[ c_i \in \mathcal{M} := \{S, L, R, F\} \]

Depending on the mode of a particular contact, a set of constraints on velocities, accelerations and reaction forces of the corresponding contact point must be satisfied. These constraints are most easily written in local contact coordinates and are summarized in Tables I and II. If the contact point is separating (S), either due to velocity or acceleration, then no reaction force is allowed, otherwise a compressive normal force is possible. Given a contact point which is not separating, we also consider its tangential motion. If the contact point is sliding left (L) or right (R) with respect to its local coordinate frame, then the tangential force must be at a maximum, otherwise the contact point is fixed (F) and the tangential force can be anywhere in the friction cone. Throughout the rest of the paper, we denote the overall contact mode of the system as a vector of individual modes for each contact

\[ \mathbf{c} := [c_1, ..., c_k] \in \mathcal{M}^k \]

In subsequent sections, we will also find it useful to encode the constraints of Tables I and II in matrix form. The following definitions are presented for a given overall contact mode of the system. Without loss of generality, we order and partition the contact Jacobian \( \mathbf{J} \) as

\[ \mathbf{J} = \begin{bmatrix} \mathbf{J}_F \\ \mathbf{J}_S \\ \mathbf{J}_L \\ \mathbf{J}_R \end{bmatrix} , \]

(6)

according to the individual contacts that are in specific modes. For equality constraints on system accelerations, we can use the appropriate rows of (4) to yield

\[ \begin{bmatrix} \mathbf{J}_F \\ \mathbf{J}_{L_n} \\ \mathbf{J}_{R_n} \end{bmatrix} \ddot{\mathbf{q}} + \begin{bmatrix} \mathbf{J}_F \\ \mathbf{J}_{L_n} \\ \mathbf{J}_{R_n} \end{bmatrix} \dot{\mathbf{q}} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} . \]

(7)

Similarly, for equality constraints on the contact reaction forces, we have

\[ \begin{bmatrix} 0 & I & 0 & 0 & 0 & 0 \\ 0 & 0 & -\mu & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & \mu & 1 \end{bmatrix} \begin{bmatrix} \mathbf{f}_F \\ \mathbf{f}_S \\ \mathbf{f}_{L_n} \\ \mathbf{f}_{L_t} \\ \mathbf{f}_{R_n} \\ \mathbf{f}_{R_t} \end{bmatrix} = 0 . \]

(8)

The remaining inequality constraints from Tables I and II take the form

\[ \begin{bmatrix} \mathbf{J}_{S_n} \\ -\mathbf{J}_{L_t} \\ \mathbf{J}_{R_t} \end{bmatrix} \ddot{\mathbf{q}} + \begin{bmatrix} \mathbf{J}_{S_n} \\ -\mathbf{J}_{L_t} \\ \mathbf{J}_{R_t} \end{bmatrix} \dot{\mathbf{q}} \geq 0 , \]

(9)

for accelerations and

\[ \begin{bmatrix} \mu & -1 & 0 & 0 & 0 & 0 \\ \mu & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} \mathbf{f}_F \\ \mathbf{f}_S \\ \mathbf{f}_{L_n} \\ \mathbf{f}_{L_t} \\ \mathbf{f}_{R_n} \\ \mathbf{f}_{R_t} \end{bmatrix} \geq 0 , \]

(10)

for contact reaction forces. Acceleration inequalities of (9) are only applicable to separating contact points with zero normal velocity and sliding contact points with zero tangential velocity as indicated in the Tables I and II.
In this paper, we also consider the possibility of imposing additional model specific linear constraints, which we divide into two categories: physical constraints and task constraints.

Physical constraints are constraints which are physically required to hold for all dynamic solutions. For example, in the flipping application presented in Section IV, we assume all legs to be massless. This induces an algebraic constraint between the applied hip control torque and contact reaction forces associated with the corresponding leg. More formally, physical constraints are assumed to be specified through the equalities

\[ A_p^q \ddot{q} = B_p^q \tau + b_p^q \]  
\[ A_f^p f = B_f^p \tau + b_f^p, \]  

as well as the inequalities

\[ N_p^q \dot{q} \geq E_p^q \tau + e_p^q \]  
\[ N_f^p f \geq E_p^f \tau + e_p^f, \]

In contrast, task constraints are user imposed conditions that are not physically necessary, but rather application specific, desired properties of dynamic solutions. In our flipping example, we use this type of constraint to impose a minimum threshold on the normal component of the reaction force for the body-ground contact. Task constraints are external to the model physics and deviate from our original goal of finding the overall dynamic response of the form (2). They restrict the solutions in task specific ways and require additional care in the characterization of contact mode ambiguities as well as solutions to the dynamics. Even though we are able to incorporate such constraints very naturally in our modeling tool, the reader should keep in mind that they result in unnatural restrictions on the identified solution domains for the dynamic response. A more detailed account of the impact of task constraints on mode ambiguities is presented in Section III-G.1. Task constraints are assumed to be specified through the equalities

\[ A_t^q \ddot{q} = B_t^q \tau + b_t^q \]  
\[ A^f_f = B_f^f \tau + b_f^f, \]

as well as the inequalities

\[ N_t^q \dot{q} \geq E_t^q \tau + e_t^q \]  
\[ N_f^f f \geq E_f^f \tau + e_f^f. \]

For clarity of presentation, we will find it convenient to merge all the equality constraints in (7), (8), (11), (12), (15) and (16) into two matrix equations for accelerations and reaction forces

\[ A_q^q \ddot{q} = B_q^q \tau + b_q^q \]  
\[ A_f f = B_f^f \tau + b_f^f. \]

Similarly, we merge all inequality constraints in (9), (10), (13), (14), (17) and (18) into two matrix inequalities

\[ N_q^q \dot{q} \geq E_q^q \tau + e_q^q \]  
\[ N_f^f f \geq E_f^f \tau + e_f^f. \]

Note that in this paper we do not consider impact models, precluding us from computing solutions to the system whenever \( \dot{x}_n < 0 \) or \( \ddot{x}_n < 0 \). Among other ramifications, Painlevé type problems [9], [18], [31] where sliding friction would result in rigid-body penetration will thus have no solution, and ambiguities due to impacts are ignored. This limits the applicability of our methods to situations where the consideration of such impacts is not important. On the other hand, the simplifications that result from our assumption are significant and useful if impacts are not critical for a particular application.

C. Form of Solutions and Outline of the Algorithm

Given a particular contact mode vector, \( c := [ c_1, \ldots, c_k ] \in \mathcal{M}^k \), and control inputs \( \tau \), we denote by \( g_c(\tau, w) \), the instantaneous dynamic response of the system within a contact mode \( c \), defined as the solution to (5), subject to the constraints (19), (20), (21) and (22). In order to construct the final form (2) of our solution, we partition its domain into a discrete number of cells, corresponding to subsets \( \mathcal{D}_c \subseteq \mathbb{R}^t \times \mathbb{R}^w \) of the global domain, wherein a particular choice of contact mode can be realized. The global form of
the dynamic response hence takes the form

\[ g(\tau, w) := \begin{cases} 
  g_{c_1}(\tau, w) & \text{if } (\tau, w) \in D_{c_1}, \\
  \vdots & \\
  g_{c_k}(\tau, w) & \text{if } (\tau, w) \in D_{c_k},
\end{cases} \]  

(23)

where we have dropped the dependence on \((q, \dot{q})\) for notational convenience. Note that each component of this global dynamic response is linear in control inputs and ambiguity variables, resulting in a function which is piecewise linear over its domain.

The primary contribution of this paper is the computation of mode specific response functions \(g_{c}(\tau, w)\) together with their domains of validity \(D_c\). We also compute projections of individual domains on to the torque axes to obtain a concise representation in the space of control inputs. Note that due to the presence of ambiguities and inconsistencies of solutions, neither the sets \(D_c\) nor their projections are guaranteed to be disjoint or even cover the entire torque space. Finally, in the presence of task constraints, we will find it useful to compute the dynamic response both with and without task constraints, allowing for a full characterization of ambiguities as described in Section III-G.

Each of the mode specific dynamic response functions in (23) as well as the associated equality and inequality constraints described in Section III-B are linear. As a consequence, our algorithm is based on three linear operations:

1. Solving a linear system (SVD)
2. Computing Support Hyperplanes (Solving a LP)
3. Polytope Projection (Fourier-Motzkin)

In particular, we start by solving the equality constraints, allowing us to compute \(g_{c}(\tau, w)\). The remaining inequality constraints describe the domain of validity for this function and can be reduced to a simple polytope in the space of control inputs and ambiguity variables through linear programming. Finally, we project the resulting polytope onto the control input space yielding the set of feasible control inputs for each mode.

The decomposition of the global problem into a set of linear subproblems also allows us to construct effective algorithms for task specific goals such as optimization over the solution set. We illustrate a specific example of such an application domain in Section IV for the dynamic self-righting of a hexapod robot. However, it is important to note that such decompositions can induce potentially prohibitive computational costs, typical of enumerative methods on problems with a large number of contacts.

### D. Computing the Mode Specific Dynamic Response

Given a contact mode, three sets of linear equality constraints must be satisfied by the unknown forces and accelerations of the system. The first set comes directly from the Lagrangian formulation in (5). The remaining two, (19) and (20), are constraints on system accelerations and forces, respectively, and originate from the contact, physical, and task constraints of Section III-B.

Our approach is to simultaneously solve these linear equations to compute \(g_{c}(\tau, w)\). In doing so, we are able to parametrically characterize force and acceleration ambiguities associated with the chosen contact mode and produce a closed form solution for the dynamic response as a function of the control inputs and ambiguity variables.

Before we proceed, we collect all linear equality constraints on contact forces and system accelerations as well as the dynamic constraint equation in a single large linear system\(^1\)

\[
\begin{bmatrix}
  A^q & 0 & 0 \\
  0 & A^f & 0 \\
  M(q) & -J^p & 0
\end{bmatrix}
\begin{bmatrix}
  \dot{q} \\
  f
\end{bmatrix}
= 
\begin{bmatrix}
  B^q & 0 & 0 \\
  0 & B^f & 0 \\
  0 & 0 & I
\end{bmatrix}
\tau +
\begin{bmatrix}
  b^q \\
  b^f \\
  b^{dyn}
\end{bmatrix}
\]  

(24)

where \(b^{dyn} := -g(q) - C(q, \dot{q}) \dot{q}\). In subsequent derivations, this equation will be used in its simpler notational form

\[
A \begin{bmatrix}
  \dot{q} \\
  f
\end{bmatrix} = B\tau + b. 
\]  

(25)

Different possible rank conditions of the matrix \(A\) result in different forms for the solutions to this linear system.

In particular, we identify four cases as all possible combinations of full column rank (f.c.r) and full row rank (f.r.r) properties of \(A\).

1. \(A\) is both f.r.r. and f.c.r.

In this case, \(A\) is invertible and there is a globally defined

\(^1\)Note that for computational efficiency, it would be beneficial to exploit the structure in the three different groups of constraints by first solving force constraints, then solving acceleration constraints, finally followed by substitution into and solution of the dynamic constraint of (5).
unique solution for \((\ddot{q}, f)\) as a function of torque, taking the form

\[
\begin{bmatrix}
\ddot{q} \\
f
\end{bmatrix} = A^{-1} B \tau + A^{-1} b.
\] (26)

2. **A is f.r.r. but not f.c.r.**

In this case, \(A\) is not invertible, and has some null space. As a consequence, even though the response function is defined for all control inputs \(\tau\), multiple solutions exist and they take the form

\[
\begin{bmatrix}
\ddot{q} \\
f
\end{bmatrix} = A^\dagger B \tau + A^\dagger b + N(A)w,
\] (27)

where \(A^\dagger\) and \(N(A)\) denote the pseudo-inverse and a basis for the null space of \(A\), respectively, and \(w\) provides a parametrization of solution ambiguities.

3. **A is f.c.r. but not f.r.r.**

In this case, \(A\) is not invertible, but does not have a null space. Consequently, solutions are unique when they exist. On the other hand, since \(A\) is not full row rank, there may be control inputs for which no solutions can be found. This happens whenever the affine subspace spanned by the right hand side of (25) is not contained in the column space of \(A\). In such cases, we must explicitly solve for the subspace of control inputs for which the system admits a solution. For the time being, let us denote this subspace as \(\tau = A^p \tau_p + b^p\) where \(\tau_p\) is a parameterization of the admissible torque subspace. The dynamic response function then takes the form

\[
\begin{bmatrix}
\ddot{q} \\
f
\end{bmatrix} = A^\dagger B \tau + A^\dagger b \\
\text{s.t. } \tau = A^p \tau_p + b^p.
\] (28)

Later in this section, we will provide an algorithm to compute \(A^p\) and \(b^p\).

4. **A is neither f.r.r. nor f.c.r.**

In this final case, not only is \(A\) not invertible, but it also has a null space leading to multiple solutions and potential non-existence of solutions due to its deficient row rank. The solution for \((\ddot{q}, f)\) takes the form

\[
\begin{bmatrix}
\ddot{q} \\
f
\end{bmatrix} = A^\dagger B \tau + A^\dagger b + N(A)w \\
\text{s.t. } \tau = A^p \tau_p + b^p.
\] (29)

For the two cases where the matrix \(A\) is row rank deficient, we need to solve for the affine subspace of control inputs that admit a solution for the dynamic response. This is easily accomplished by rearranging the linear system (25) and considering the control torques as a variable

\[
\begin{bmatrix}
A & B \\
\ddot{q} & f
\end{bmatrix} = b.
\] (30)

Using the notation \(\{\}_\tau\) to refer to the last rows of coefficient matrices in the solution, we have

\[
\tau = \left\{ \left[ \begin{array}{c} A \\ B \end{array} \right] \right\} \tau_p + \{N(\begin{array}{cc}
A & B
\end{array})\}_\tau \tau_p
\] (31)

concisely parameterizing admissible control inputs for which the dynamics admit an instantaneous solution. Note that the potential reduction in the actuation freedom through the smaller parameterization \(\tau_p\) must be taken into account in computing the domain of \(g_e(\tau, w)\) in the next section. This can either be done by rewriting the domain on the reduced set of coordinates or simply keeping track of the reduced torque subspace.

**E. Computing the Domain of the Dynamic Response**

As described in the previous section, the solutions to the Lagrangian dynamics under equality constraints associated with a particular contact mode yields the functional form of the local dynamic response function \(g_e(\tau, w)\), mapping control inputs and ambiguity variables to system accelerations and reaction forces. It still remains, however, to incorporate all inequality constraints introduced in Section III-B.

Our interpretation of these remaining constraints takes the form of a restriction on the functional domain of \(g_e(\tau, w)\). As all equality and inequality constraints are linear, this restricted domain \(\mathcal{D}_e\), can be effectively represented as a convex polytope in the space of control inputs and ambiguity variables. Based on this general representation of the domain, we also compute its projection \(\mathcal{T}_e := \{ \tau \mid (\tau, w) \in \mathcal{D}_e \}\) onto the space of control inputs. This projection characterizes the set of control inputs for which the contact mode has a solution and is useful for
determining when there are solution ambiguities between contact modes.

Similar to our treatment of equality constraints, we group both reaction force and acceleration inequalities of (22) and (21) into a single system

\[
\begin{bmatrix}
N^{\text{eq}} & 0 & E^{\text{eq}} \\
0 & N^{f} & E^{f}
\end{bmatrix}
\begin{bmatrix}
\dot{q} \\
f \\
\tau
\end{bmatrix}
\geq
\begin{bmatrix}
e^{\text{eq}} \\
e^{f}
\end{bmatrix}.
\] (32)

The appropriate choice out of the four possible closed form solutions in (26), (27), (28), or (29) from the previous section can be directly substituted in this system of inequalities, effectively eliminating the generalized system accelerations \(\dot{q}\) and contact forces \(f\). We are then left with a set of linear inequality constraints on the control inputs \(\tau\) and ambiguity variables \(w\), taking the form

\[
N
\begin{bmatrix}
\tau \\
w
\end{bmatrix}
\geq e.
\] (33)

Solutions to this linear inequality system correspond to the set of control torques and ambiguity variables for which the resulting reaction forces and system accelerations simultaneously satisfy all equality and inequality constraints described in Section III-B, yielding the desired domain \(D_c\).

In some cases, the system of inequalities in (32) may not be a minimal representation of \(D_c\) since it may include redundancies and overlapping constraints. Inequality, or half-space, constraints which directly determine the boundary of a polytope are called \textit{supporting} constraints. A minimal representation for \(D_c\) is one in which all half-space constraints are supporting. Reduction of (32) to such a minimal representation can be accomplished by solving a linear program for each individual inequality.

Consider the \(i^{th}\) row of (33),

\[
n^{i}
\begin{bmatrix}
\tau \\
w
\end{bmatrix}
\geq e_{i}.
\]

In order to determine whether this is a supporting hyper-plane, we solve the linear program

\[
\begin{align*}
\min & \quad x \\
\text{s.t.} & \quad \begin{bmatrix}
N & 1
\end{bmatrix}
\begin{bmatrix}
\tau \\
w
\end{bmatrix}
\geq e \\
\text{and} & \quad \begin{bmatrix}
n^{i} & 0
\end{bmatrix}
\begin{bmatrix}
\tau \\
w
\end{bmatrix}
= e_{i}.
\end{align*}
\]

The constraint under consideration yields a supporting half-plane if and only if the optimal solution \(x\) to this linear program is zero [34]. Performing this test on all inequality constraints, we can generate a minimal representation of \(D_c\). Not surprisingly, if there are no supporting constraints, then \(D_c = \emptyset\).

Once we have computed a minimal representation of \(D_c\), we then compute its projection \(T_c\) on to the \(\tau\) axes, shown in Figure 1. This projection may be accomplished by a polytope projection technique such as Fourier-Motzkin [15]. The process is similar to Gaussian elimination but deals with linear inequalities rather than equalities. Briefly, elimination of a variable with the Fourier-Motzkin technique involves adding together all permutations of inequalities with coefficients of opposite sign on the variable to be eliminated. The inequalities are scaled by a positive scalar so that these opposite sign coefficients cancel, thus eliminating the particular variable. The projection process often produces redundant constraints and an additional reduction through linear programming may be required to produce a minimal representation.
Normal Velocity | Tangential Velocity | Modes
---|---|---
\(\dot{x}_n > 0\) | \(- - -\) | S
\(\dot{x}_n = 0\) | \(\dot{x}_t > 0\) | S,R
\(\dot{x}_n = 0\) | \(\dot{x}_t < 0\) | S,L
\(\dot{x}_n = 0\) | \(\dot{x}_t = 0\) | F,S,L,R

**TABLE III**
Kinematically feasible contact modes based on contact point velocity.

**F. Enumeration of Modes and Kinematic Feasibility**

The most general form of the global dynamic response function (23) requires the consideration of all \(|\mathcal{M}_k| = 4^k\) possible contact modes of the system. Using the algorithms presented in Sections III-D and III-E, this would involve computing functions \(g_c(\tau, \mathbf{w})\) and their domains \(\mathcal{D}_c\) for each contact mode.

Fortunately, we can significantly decrease the number of contact modes for which these quantities have to be computed by taking into account kinematic components of the constraints in Section III-B. For any given contact, its normal and tangential velocities computed through the jacobian map of (3) helps us determine which modes are kinematically feasible. Table III-F summarizes all possible velocity based eliminations.

In addition to local eliminations for each contact, it may be possible to rule out contact modes based on global motion constraints on system kinematics. For instance, distances between multiple contact points on the same rigid body are constrained to remain constant, potentially eliminating certain overall combinations of contact modes. Computationally, the velocity and acceleration constraints from Tables I and II can be combined as a linear programming problem across all contact points to determine whether a particular mode is feasible. This type of elimination is especially useful for systems in which the number of contacts is large with respect to the internal degrees of freedom.

Local and global elimination of infeasible modes in this manner results in a smaller set of contact modes to be considered in our algorithm. We define the resulting collection of contact modes to be the set of *kinematically feasible contact modes*, denoted by \(\mathcal{M}_p \subseteq \mathcal{M}_k\). Note that the contents of this feasible set depend only on the current system configuration and velocities \(\mathbf{q}\) and \(\dot{\mathbf{q}}\).

**G. Characterizing Solution Ambiguities**

A typical problem associated with Coulomb frictional models is potential ambiguities in computing solutions. In Section III-D, we have been able to parameterize potential acceleration and force ambiguities within a particular contact mode by introducing a vector of ambiguity variables, \(\mathbf{w}\). An additional possible source of ambiguities is in determining the contact mode realized by a particular choice of control inputs. In this section, we carefully characterize each of these two types of ambiguities, illustrated in Figure 2, and present methods useful in the design of controllers that can avoid associated problems.

![Fig. 2](image)

Fig. 2. The two types of solution ambiguities. The figure on the left illustrates an ambiguity between two contact modes, manifested as an intersection of the control input domains \(\mathcal{T}_c\). The figure on the right illustrates ambiguities within a contact mode, characterized by the feasible range in the variable \(\mathbf{w}\) for a given control input.

Our distinction between solution ambiguities within a particular mode and contact mode ambiguities closely parallels our decomposition of the problem into the computation of mode specific functions \(g_c(\tau, \mathbf{w})\) and the enumerative definition for the global dynamic response in (23).

For contact mode ambiguities, we present a method in Section III-G.1 to identify sets of control inputs which are guaranteed to unambiguously achieve a desired contact mode. This can be particularly useful for tasks which crit-
ically rely on the realization of particular modes, such as during climbing with a snake robot by ensuring that there is a set of supporting contacts which are fixed relative to the environment.

For ambiguities within a contact mode, the conditions provided in Section III-D do not necessarily result in ambiguous reaction forces and accelerations in all cases. In Section III-G.2, we provide certain conditions for the degeneracy of the polytope describing the domains of mode specific dynamic response functions that are necessary for concluding the presence of such ambiguities. We also give a number of illustrative examples to give some intuition towards possible causes of multiplicity in force and acceleration solutions.

G.1 Contact Mode Ambiguities

In Section III-E we presented an algorithm to compute the set $T_c$ of control inputs consistent with the realizations of solutions in a given contact mode. Non-empty intersections between these domains for different contact modes indicates that they are solutions to both contact for the intersecting set of control torques. The result is a contact mode ambiguity wherein it is not possible to conclude from the model alone which contact mode will be physically realized for the given choice of control inputs.

For certain applications, controllers may want to stay away from such ambiguities by avoiding control inputs for which the model is unable to yield a unique solution. Therefore, we would like to compute unambiguous domains of control inputs for each contact mode.

Consider a particular pair of contact modes $c_i$ and $c_j$. Control inputs for which there is an ambiguity between these modes can be represented by the intersection of the corresponding domains, $T_{c_i} \cap T_{c_j}$. This intersection is easily computed by taking the union of the associated linear inequality systems. Similar to our reduction of domains in Section III-E, the resulting set of inequalities can be reduced to a minimal representation through linear programming.

Once all such pairwise intersections are computed, the unambiguous domain $T_{c_i}^*$ for a contact mode $c_i$ is defined as

$$T_{c_i}^* := T_{c_i} - \bigcup_{e \in (\mathcal{M}_p-c)} (T_e \cap T_{c_i}),$$

which will, in general, be a non-convex volume in the space of control inputs.

![Fig. 3](image1.png)

Fig. 3. The figure on the left illustrates a contact mode ambiguity which can be properly identified in the absence of the task constraint. The situation illustrated in the figure to the right, however, fails to reveal this ambiguity due to the task constraint.

One important pitfall in computing the unambiguous domain $T_{c_i}^*$, is the consideration of task constraints. Our goal is to identify all ambiguities that are physically plausible. However, task constraints are externally imposed on the system and potentially eliminate solutions that may still be physically realizable. Figure 3 illustrates a scenario in which the consideration of task constraints prior to the computation of $T_{c_i}^*$ results in the incorrect elimination of a contact mode ambiguity. In order to avoid this problem, domains for identifying contact mode ambiguities must be computed prior to imposing task constraints.

![Fig. 4](image2.png)

Fig. 4. An actuated two-link mechanism. Indeterminate compressive loads on the links can create an ambiguity between sliding downward and static equilibrium for certain control torques.

Figure 4 portrays an illustrative example of mode ambiguities for a two link planar climbing robot. Compressive loads along each of the links cannot be uniquely determined. Furthermore, for large compressive loads, frictional
forces can negate the gravity force and keep the system fixed in place. In contrast, for lower compressive loads the frictional forces may be insufficient to support the system, allowing it to slide downward. The result is a contact mode ambiguity between fixed and downward sliding modes for all contacts.

G.2 Ambiguities within a particular contact mode

Whenever $\mathbf{A}$ in the merged equality constraints of (25) does not have full column rank, force and acceleration ambiguities may occur within a contact mode. In such cases, we parameterize the set of possible solutions with a vector of ambiguity variables, $\mathbf{w}$, whose ranges are also restricted through the computation of the feasibility domain $D_c$.

![Fig. 5. A rigid table with indeterminate tangential forces](image)

Figure 5 illustrates an example where a rigid planar table with two legs is positioned on a flat floor. If the contact points are assumed to be fixed, the normal components of the ground reaction forces are known, but the tangential loads cannot be uniquely determined. In this case, the accelerations are uniquely determined but there is an ambiguity in the contact reaction forces.

Similarly, Figure 6 portrays a planar ball bearing in contact with four flat surfaces, illustrating a situation wherein there is a coupled ambiguity in computing both the reaction forces and accelerations. Under the assumption that the ball has nonzero rotational velocity and all contact points are sliding, the unknown normal reaction forces result in ambiguous torsional load from frictional forces and hence non-unique solutions for the reaction forces and the rotational acceleration of the ball.

These two examples also illustrate that ambiguities within a contact mode may be purely in reaction forces, or in both system accelerations and reaction forces. Further analysis on the structure of $\mathbf{N}(\mathbf{A})$ as defined in Section III-D would be necessary for any conclusions in this context. For certain applications, such as the maximal thrust controller for flipping, it may be important to establish the uniqueness of solutions in accelerations while ambiguities in reaction forces can be tolerated.

Finally, a necessary condition for the presence of ambiguities within a mode is the non-degeneracy of the feasible domain $D_c$. In cases where the polytope representation for this domain collapses in the direction of the ambiguity variables, there will be no ambiguities even though the form of $g_c(\tau, \mathbf{w})$ explicitly incorporates the vector $\mathbf{w}$. Note, however, that this corresponds to a very fragile situation where even small changes in parameters may result in the expansion of the domain back into a non-degenerate volume, reintroducing multiple solutions.

H. Computational Complexity

In this section, we report on the average time complexity of our algorithm, particularly focusing on its dependence on the number of contacts $k$, in order to characterize its practical applicability.

We present the complexity analysis of our algorithm in two components: Solving for the dynamic response within a contact mode and the enumeration of feasible modes. Not surprisingly, the dominant complexity arises from the contact mode enumeration and is exponential in the number of contacts $k$ as well as the dimension of the space ambiguities within a contact mode, $w$. Nevertheless, the algorithm complexity scales as a cubic polynomial in $q$ and $t$. 
H.1 Mode-Specific Dynamic Response and Domain

In the absence of external constraints, solving the linear system in (25) for $g_c$ requires the Singular Value Decomposition (SVD) of a matrix with dimensions $(q+2k) \times (q+2k)$. When $A$ is not full row rank, an additional step is needed to find the pseudo-inverse of a matrix with dimensions $(q + 2k) \times (q + 2k + t)$, resulting in an overall complexity of $O((q + 2k + t)^3)$, or cubic in the largest dimension of the matrix [8]. We specifically focus on the complexity with respect to the number of contacts, yielding $O(k^3)$ for the solution of all equality constraints.

In solving for the domain associated with a particular contact mode, two inequality constraints for each contact must be considered in the worst case. The resulting matrix $N$ thus has dimensions $(2k) \times (t + w)$. The reduction of this system to a minimal representation through the Simplex algorithm for solving linear programs is known to have an exponential worst case running time. However, for our analysis, we use the expected running time of the algorithm, which is only linear in the number of constraints [34]. Since a linear program must be solved for each of the $2k$ inequality constraints, the expected running time for this step, once again focusing on $k$, is $O(k^2)$.

In cases where there are ambiguities within a mode, polytope projection is performed. The Fourier-Motzkin projection technique is known to produce many spurious inequality constraints, with an upper bound of $O(m^2)$ for the number of resulting constraints, where $m$ is the number of inequalities prior to the projection [15]. Starting with $2k$ constraints, $w$ projections are needed, resulting in a complexity of $O(k^{2w})$ which is exponential in the number of ambiguity variables. Finally to reduce this system to a minimal representation through linear programming, results in a total expected running time for this step as $O(k^{4w})$.

H.2 Enumeration of Feasible Contact Modes

The number of possible contact modes for a multi-rigid-body system is $4^k$. The worst case is when all contact points are stationary, forcing our algorithm to consider all possible modes. In contrast, the best case is when all contacts have nonzero velocities, resulting in reductions in feasible contact modes to $2^k$. Both cases, are exponential in the number of contacts.

Each feasible mode requires the computation of the mode specific dynamic response, whose average complexity was presented in the previous section. The overall complexity for our algorithm hence becomes $O(2^k (4^w + k^3))$, which naturally preserves the exponential complexity resulting from the mode enumeration.

Despite certain improvements resulting from the analysis of kinematic feasibility to improve on the exponential running time, the general problem of determining contact modes is generally known to be exponential [4]. Even though some algorithms such as Lemke’s [16] are widely used in building multi-rigid-body simulations, and are capable of finding single solutions without the exponential complexity, they sacrifice completeness and the ability to accurately identify ambiguities, which are critical components for the problems we are interested in. The complexity of our proposed methods is not significantly worse than currently known algorithms for accurate modeling of multi-rigid-body systems under frictional contact. Even though our ability to produce concise representations of feasible sets of control inputs for any given contact mode induces additional, potentially exponential, elements in the overall complexity of our algorithm, we believe that their utility in the design of model-based controller is still valuable.

IV. Dynamic Flipping with RHEx

Design and analysis of dynamic robot behaviors with multiple frictional contacts is a challenging problem. Two of the authors previously investigated an example of such a task — dynamical recovery of correct body orientation for a hexapod robot [30]. However, the “blind”, model-based controller design in this previous approach makes very rigid assumptions about the contact modes on which the underlying models are based. Furthermore, the absence of explicit constraints to ensure that all assumed contact modes are realized, results in the overall inaccuracy of the models and dimished performance of the resulting controller.

In this section we apply the general modeling tool for dy-
namical systems with multiple contacts developed in preceding sections to build a dynamical flipping controller for a planar hexapod. Our controller design is very close in principle to the method described in [30]. However, in our new approach, we do not make rigid assumptions regarding contact modes, ensuring the validity of the resulting strategy on a much larger set of states.

A. Overview of Previous Models and Controllers

Figure 7 illustrates a generic planar flipping model whose constrained instances constitute the basis for the controller designs in [30]. Three massless rigid legs — each representing a pair of RHex’s legs — are attached to a rectangular rigid body with mass \( m \) and inertia \( I \). The attachment points of the legs are fixed at \( d_i \), along the midline of the rectangular body. This line also defines the orientation of the body, \( \alpha \), with respect to the horizontal. The body length and height are \( 2d \) and \( 2h \), respectively. The body-ground and toe-ground contacts are assumed to experience Coulomb friction with coefficients \( \mu_b \) and \( \mu_t \), respectively.

All flipping controllers for RHx adopt the same general structure. Starting from a stationary position on the ground, the robot quickly thrusts itself upward while maintaining contact between the ground and the endpoint of its body as the front and middle legs successively leave the ground. Depending on the frictional properties of the ground contacts, this thrust generates body kinetic energy that may in some cases be sufficient for a successful flip.

The performance of the flipping controller is predominantly determined by the amount of energy that can be injected into the system through the thrust phase. Even in cases where a single thrust is not sufficient, it is possible to use multiple bounces to build up sufficient kinetic energy and successfully flip over. Ensure maximal acceleration during the thrust phase produces the best performance. In this paper, we concentrate on thrust controllers that utilize detailed models which predict how the robot can elicit ground reaction forces in consequence of hip torques operating at different body states and assuming varying leg contact configurations.

In using such models, the blind controller design in [30] was forced to consider only a small number of contact modes due to the absence of a general tool to uniformly handle the set of all possible equations of motion under different contact conditions. The choice of particular contact modes to be modeled was primarily motivated by empirical studies on open-loop flipping algorithms. In particular, two constrained models were used. The first model was derived under the assumption that the front and middle legs slide backwards whereas the body and the rear legs slide forward, all maintaining contact with the ground throughout flipping. In contrast, the second model assumed that the rear toes were stuck on the ground with the body sliding forward and the middle and front legs sliding backwards. These two particular models were chosen primarily based on empirical observations of flipping experiments, the majority of which exhibited initial backward sliding of the rear toe followed by stiction towards the end of each flip. Due to the highly empirical nature of contact mode estimation, we will term the resulting controller the “blind” model-based flipping controller.

The derivation of the equations of motion for these models was done through a free body analysis wherein the force and moment balance equations for each leg in contact with the ground as well as the body link yield the matrix equation

\[
A v = B \tau + b.
\]

as a function of the unknown force and acceleration vector \( v \) and state dependent matrices \( A \), \( b \) and \( B \). For the model with sliding rear toe, we have \( v_s := [f_{n_1}, f_{n_2}, f_{n_3}, \ddot{\alpha}, f_{n_1}, \dot{y}_0]^T \), whereas for the model with the fixed rear toe, we define \( v_f := [f_{n_1}, f_{n_2}, f_{n_3}, \ddot{\alpha}, f_{n_1}, f_{t_1}]^T \).

In this formulation, a number of the usual anomalies
associated with Coulomb friction models are observed as singularities in the matrix $A$ or inconsistencies in individual balance equations. However, in [30], the consideration of only a few of all possible contact modes was insufficient to reliably and completely identify all ambiguities and inconsistencies in modeling system behavior. In contrast, the general method described in Section III uniformly considers all kinematically feasible contact modes, ensuring sound and complete identification of all friction related anomalies in the model.

B. Current Model and Extensions

B.1 Lagrangian Formulation of the Dynamics

The general planar model illustrated in Figure 7 also underlies our current design for model based flipping controllers. However, in contrast to the Newton-Euler formulation adopted in [30], we present a Lagrangian formulation of the same dynamical system as an instance of the general framework of Section III-A.

We will find it convenient to work in the generalized coordinates $q := [y_b, z_b, \alpha]^T$ for the unconstrained planar system. The dynamics are those of a simple planar rigid body under external force and torque inputs, and take the form

$$
\begin{bmatrix}
  m & 0 & 0 \\
  0 & m & 0 \\
  0 & 0 & I
\end{bmatrix}
\ddot{q} + \begin{bmatrix}
  0 \\
  -mg \\
  0
\end{bmatrix} = (D_q x)^T f, \quad (34)
$$

where the jacobian of contact coordinates with respect to model coordinates is derived with the hip angles $\phi_i$ kept fixed. In contrast to (5), the control inputs in this case do not directly act on the generalized coordinates but are rather applied to the hip angle coordinates $\phi_i$. As we assume all legs to be massless, these hip torque inputs are incorporated into the equations of motion as algebraic equality constraints on the contact reaction forces, taking the form

$$(D_\phi x)^T f = \tau. \quad (35)$$

Given a contact mode vector $c$ and a control input torque vector $\tau$, the equations of motion and contact reaction forces can then be found by solving (34) under the constraints (35) as well as the contact mode constraints of Section III-B.

B.2 Maximal Thrust Across All Contact Modes

As outlined in Section IV-A, the main challenge in the design of flipping controllers is to inject as much kinetic energy into the pitch degree of freedom as possible during the thrust phase. Although not “optimal” in a formal sense — the translational degree of freedom if the body is not considered in the optimization, this approach effectively targets the task at hand: maximal pitch acceleration of the body to overcome the potential energy barrier of the vertical configuration.

In the absence of contact constraints with frictional nonlinearities, obtaining maximal thrust for the resulting purely continuous system would have been as simple as solving a single linear programming problem instance to maximize $\ddot{\alpha}$. However, the flipping behavior critically relies on frictional contact interactions with the environment, causing solutions for system accelerations to be piecewise linear in the control inputs. Each possible contact mode must now be individually considered, together with the additional constraints it imposes on the feasible set of torques.

In light of these observations, our controller design attempts to be as general as possible by considering all possible contact modes, but conservative enough to ensure that the physical system is guaranteed to yield the predicted response.

Our controller enumerates all possible contact modes and solves a linear programming problem to maximize the pitch acceleration $\ddot{\alpha}$, subject to external constraints on control inputs — such as motor torque limitations — as well as the feasibility constraints of Section III-E arising from the assumed contact mode. Formally, given the current state $(q, \dot{q})$ and a particular contact mode $c$ which is kinematically feasible, we compute control inputs to yield the maximal pitch acceleration response as

$$
\tau^*_c := \operatorname{argmax}_{\tau \in \mathcal{T}_c} (\ddot{\alpha}_c(\tau))
$$

and

$$
\ddot{\alpha}^*_c := \ddot{\alpha}_c(\tau^*_c),
$$
where $\mathcal{T}_c$ denotes the set of feasible torques as described in Section III-E.

In constraining $\mathcal{T}_c$, we only consider regions of the torque space that unambiguously guarantee the contact mode $c$, using the methods described in Section III-G.1. In addition, we impose a task constraint such that the normal component of the ground reaction force is always kept greater than a manually chosen threshold to ensure continued contact of the body with the ground, even in the presence of model inaccuracies and sensor noise $^3$.

Following this formulation, we can consider all the kinematically feasible contact modes in the set $\mathcal{M}_f$, yielding the solution to the global problem as

$$c^* := \arg\max_{c \in \mathcal{M}_f} (\vec{\alpha}_c^*)$$

$$\tau = \tau_{c^*}.$$

C. Simulation Studies

The blind controller used in [30] was successfully deployed on RHex and extensive experimental evidence was given to establish the performance and prediction accuracy of underlying models. RHex’s limited sensor suite — an onboard fiber-optic gyro — currently only yields body orientation measurements and cannot supply translational coordinates and velocities of its body. Practical deployment of the blind controller was made possible by a number of assumptions and simplifications, reducing the state dependence of model equations to only the pitch degree of freedom in all cases. However, the current controller is based on a more complete formulation of contact modes and the associated dynamics does not admit similar simplifications. Furthermore, the current implementations with the general method require significantly more computational resources and are not feasible for practical deployment at this time.

Consequently, in this paper, we use simulation studies to illustrate the accuracy and robustness of the new approach and present comparisons to simulated versions of the blind controller. In doing so, we also present evidence to ensure the validity of our simulation environment with respect to previous flipping experiments on RHex.

$^3$Motivations for this constraint are detailed in [30]

C.1 Simulation Environment

The planar model that underlies all our simulations in this paper is morphologically similar to the model presented in Section IV-A but differs in three major aspects.

First, all three legs incorporate radial compliance and damping in contrast to the rigid leg links on the model we use to design our controllers. This enables us to more accurately capture RHex’s behavior wherein the compliance in the legs has significant impact on behavior in certain configurations.

Second, we model the feet independently by incorporating small point masses on the toes. Forces transmitted through the leg, frictional forces and gravity act on the toes and govern their motion. Both the non-rigid coupling between the toes and the body as well as the lack of rotational inertia of the toes allows us to avoid ambiguities and inconsistencies that are typical of frictional Coulomb contacts, and hence yield a reliable simulation environment free of singularities.

Finally, we adopt a penetration based model for the body-ground contact to eliminate the need for explicit modeling of impacts as well as Coulomb model induced anomalies such as Painlevé’s problem. The normal ground reaction force is computed as a function of body penetration distance and velocity, whereas the horizontal force adopts a pure Coulomb model. This extension also has the benefit of approximating the padded protective skin on RHex whose deformations are most likely manifested in experiments as deviations from the rigid model and inaccuracies in the kinematic assumptions of state estimators.

Figure 8 together with the kinematic and dynamic parameters in Table IV specify the model used in our simulation.

Fig. 9. Validation of simulation accuracy with respect to experiments on RHex. Solid lines show simulated flipping, whereas dashed lines are experimental measurements of RHex flipping on linoleum, both under the action of the old, model-based controller with $\mu_t = 0.39$.

Figure 9 illustrates a comparison between a flipping simulation with the compliant model described in this section and an example flipping experiment on RHex (see Extension 1), both under the action of the blind model-based controller described in [30]. Most of the differences arise from the torsional compliance of RHex’s legs which introduce significant delay in the transmission of motor torque to the body. In contrast to simulations presented in [30] which directly use the rigid model, the compliant model with toe masses more accurately simulates the early liftoff of the legs as well as the true stiction behavior of the rear toe.

C.2 Performance of Previous Controllers

In this section, we present simulation results with the blind controller that illustrate cases in which its rigid assumptions regarding contact modes are inaccurate. In particular, we show that the performance of the indirect detection of rear toe stiction based on measurements of pitch acceleration largely depends on the closeness of surface parameters to empirical tuning conditions. In contrast, the new controller inherently handles contact mode induced switching of models and does not rely on an empirically tuned filter.

Figure 10 illustrates the baseline performance of the blind controller on linoleum, characterized by a relatively low friction coefficient at $\mu_t = 0.39$. This corresponds to the conditions in which the toe stiction detection algorithm was tuned and hence yields relatively accurate timing for the switching of models.

![Fig. 10. Flipping with the blind model-based controller with low toe friction $\mu_t = 0.39$. Top half illustrates model prediction and the actual simulation data for the pitch acceleration, whereas the bottom half portrays the progression of contact modes for all the legs and the body. See Extension 2 for the associated animation.](image)

In contrast, Figure 11 illustrates the blind controller on a surface with higher coefficient of friction such as asphalt with $\mu_t = 0.6$. In this case, the rise in the pitch acceleration due to the stiction of the rear toe is not sufficient to trigger the model switch in a timely manner. Instead, the controller maintains a wrong assumption about the contact mode until the body-ground contact comes to a halt much later, inducing the necessary sharp change in the pitch acceleration. The consequent delay in the switch to the model
with stuck rear toe usually results in degraded thrust performance as the sliding toe model is more conservative and applies much lower torque actuation to the rear leg.

C.3 Coping with Model Inaccuracies

Section III-F describes a step in our contact modeling algorithm which permits computationally efficient elimination of contact modes that are physically impossible based on the kinematic maps (3) and (4) for contact velocities and accelerations. Not surprisingly, this procedure is very sensitive to errors in the kinematic model with respect to the physical system under consideration and can lead to erroneous elimination of some contact modes. In practice, equality conditions on components of contact velocities are almost always guaranteed to fail and membership tests against intervals around the desired quantities is a much more robust method against inevitable model inaccuracies and sensor noise. Our controller design and the optimization across feasible contact modes presented in Section IV-B.2 is particularly vulnerable to such errors which can lead to sub-maximal thrust solutions and controller chatter.

Our approach is to relax the conditions in Table III-F to prevent overly aggressive elimination of feasible contact modes. We introduce thresholds $v^0_i$ on the velocities of each toe such that whenever $|\dot{x}_t^i| < v^0_i$, we refrain from eliminating any modes for that contact. Our choice of $v^0_i$ is based on simulations to identify the relative inaccuracy of the rigid flipping model of Section IV-A with respect to the simulated model with leg compliance and body penetration described in Section IV-C.1. Figure 12 illustrates rigid model predictions of toe velocities against simulated toe velocities through a typical flipping run with the blind controller. In order to determine the thresholds $v^0_i$ for toe and body contacts, we consider intervals wherein the contact is fixed in simulation and identify the range of model predictions for velocities. All flipping experiments reported in [30] as well as simulations of the blind and new model-based controllers yield trajectories that are kinematically very similar. As a consequence, we use the thresholds recovered from Figure 12 for all simulations of our new controller.

C.4 Performance of the New Controller

As described in Section IV-B.2, the application of the general method for contact mode analysis to the design of a flipping controller allows the consideration of all kinematically feasible possibilities in finding the maximal thrust torque. As a consequence, the new controller does not need to make any task specific assumptions on the progression of body or leg contact states and hence has a much larger domain of validity with respect to variations in surface conditions.

Even compared to the blind controller operating under the low friction conditions of Figure 10 for which it was tuned, Figure 13 illustrates that the new controller’s estimate of contact modes is much more accurate. Notably, it was even able to match the renewed right sliding of the
rear toe towards the end of the flip around \( t = 0.45s \).

Fig. 13. Flipping with the new controller with low toe friction \( \mu_t = 0.39 \). See Extension 4 for the associated animation.

The robustness of the new controller is much more evident on high friction surfaces as illustrated in Figure 14. In contrast to the poor predictive performance of the blind controller in Figure 11, the new controller is able to find much more accurately the point in which the stiction of the rear toe yields the maximal thrust and appropriately adjusts the hip torques. As a result, the resulting thrust phase is more effective with a 8% improvement in the time it takes to complete a flip.

Fig. 14. Flipping with the new controller with high toe friction \( \mu_t = 0.6 \). See Extension 5 for the associated animation.

V. CONCLUSION AND FUTURE WORK

A. Conclusion

Control of robotic systems subject to frictional constraints can be a challenge due to the non-linearities and physical modeling challenges inherent in modeling frictional contact. In this paper we model such systems as multi-rigid-bodies subject to coulomb friction and linear complementarity constraints.

We develop a computational framework to compute the instantaneous dynamic response of such systems as a function of the control torque. The algorithm developed in particular characterizes all possible dynamic solutions of the system, thus allowing for identification of areas of ambiguity in the dynamic response. Our algorithm decomposes the dynamic response by contact mode, thus dividing the computation of the system dynamics into linear sub-problems.

Based on the computed instantaneous dynamic response, a controller is generated for a flipping application which optimizes the system behavior with respect to the instantaneous dynamics, in particular maximizing the pitch acceleration subject to additional linear constraints.

B. Future Work

An obvious extension to the work is a treatment of impact, which may be a crucial aspect of controlling some robotic systems subject to frictional contact. Of course, the extension to three dimensions is also important, and will come with increased computational cost. Since the coefficient of friction is often not well known, or even constant as a function of time, an extension of these control techniques with some measure of provable robustness to variations in friction coefficient, and possibly other kinematic or dynamic quantities, would be an important extension.

Practically, the issue of inexact or incomplete state measurement becomes important when applying this control method on actual robot systems. In particular, the prediction of contact point velocities based on incomplete or noisy sensor measurements is crucial, especially when the contact point velocity is low, since the model dynamics undergoes a change of mode on the measure zero set of the sticking contact point.

ACKNOWLEDGMENT

The authors would like to thank Devin Balkcom, Siddhartha Srinivasa, and Howie Choset for com-
ments on the algorithm. This work was supported in part by ARO grant DAAD19-02-1-0383 and DARPA grants DARPA/SPAWAR N66001-03-C-8045, DARPA/ONR N00014-98-1-0747 and DARPA/SPAWAR N66001-00-C-8026.

INDEX TO MULTIMEDIA EXTENSIONS

Extension 1. Video: LinoleumSingleShot.mpg. High speed video (150fps) of RHex 1.5 flipping on linoleum with the blind controller.

Extension 2. Video: blind_0.39.mpg. Slow motion animation of a planar flipping simulation with the blind controller on a surface with $\mu_t = 0.39$

Extension 3. Video: blind_0.6.mpg. Slow motion animation of a planar flipping simulation with the blind controller on a surface with $\mu_t = 0.6$

Extension 4. Video: improved_0.39.mpg. Slow motion animation of a planar flipping simulation with the improved controller on a surface with $\mu_t = 0.39$

Extension 5. Video: improved_0.6.mpg. Slow motion animation of a planar flipping simulation with the improved controller on a surface with $\mu_t = 0.6$

Extension 6. Data: data_scripts.tar.gz. Simulation code, data files and visualization scripts for all the experiments and simulations. Please see README.txt in this archive for details on the format of data files and the usage of associated scripts.
